

- Las mortalidades observadas al inicio del cuarto experimento fueron asociadas a la presencia de cantidades excesivas de zooplancton en las lagunas de estabilización, en el período previo a la siembra de peces. A su vez, el zooplancton fue promovido por un excesivo aporte de nutrientes, tanto en el sistema de estabilización, como en los estanques de cultivo.
- A fin de evitar un ingreso excesivo de nutrientes, sería recomendable, que tanto el sistema de estabilización como los estanques, sean sometidos a un período de estabilización después del llenado y antes de proceder a la siembra de peces. Este período de estabilización deberá ser de aproximadamente 15 días, empezando a contar recién cuando la infiltración se halla reducido.
